# Chapter 1

## Introduction

This document provides a specification of the *Whiley Programming Language*. Whiley is a hybrid imperative and functional programming language designed to produce programs with as few errors as possible. Whiley allows explicit specifications to be given for functions, methods and data structures, and employs a *verifying compiler* to check whether programs meet their specifications. For example, Whiley would be ideally suited for use in *safety critical systems*. However, there are many benefits to be gained from using Whiley in a general setting (e.g. improved documentation, maintainability, reliability, etc). Finally, this document is *not* intended as a general introduction to the language, and the reader is referred to alternative documents for learning the language<sup>[1]</sup>.

### 1.1 Background

Reliability of large software systems is a difficult problem facing software engineering, where subtle errors can have disastrous consequences. Infamous examples include: the Therac-25 disaster where a computer-operated X-ray machine gave lethal doses to patients<sup>[2]</sup>; the 1988 worm which reeked havoc on the internet by exploiting a buffer overrun<sup>[3]</sup>; the 1991 Patriot missile failure where a rounding error resulted in the missile catastrophically hitting a barracks<sup>[4]</sup>; and, the Ariane 5 rocket which exploded shortly after launch because of an integer overflow, costing the ESA an estimated \$500 million<sup>[5]</sup>.

Around 2003, Hoare proposed the creation of a *verifying compiler* as a grand challenge for computer science<sup>[6]</sup>. A verifying compiler “uses automated mathematical and logical reasoning to check the correctness of the programs that it compiles.” There have been numerous attempts to construct a verifying compiler system, although none has yet made it into the mainstream. Early examples include that of King<sup>[7]</sup>, Deutsch<sup>[8]</sup>, the Gypsy Verification Environment<sup>[9]</sup> and the Stanford Pascal Verifier<sup>[10]</sup>. More recently, the Extended Static Checker for Modula-3<sup>[11]</sup> which became the Extended Static

Checker for Java (ESC/Java) — a widely acclaimed and influential work<sup>[12]</sup>. Building on this success was JML and its associated tooling which provided a standard notation for specifying functions in Java<sup>[13]</sup>. Finally, Microsoft developed the Spec# system which is built on top of C#<sup>[14]</sup>.

## 1.2 Goals

The Whiley Programming Language has been designed from scratch in conjunction with a verifying compiler. The intention is to provide an open framework for research in automated software verification. The initial goal is to automatically eliminate common errors, such as *null dereferences*, *array-out-of-bounds*, *divide-by-zero* and more. In the future, the intention is to consider more complex issues, such as termination, proof-carrying code and user-supplied proofs.

## 1.3 History

Development of the Whiley programming language begun in 2009 by Dr. David J. Pearce, at the time a lecturer in Computer Science at Victoria University of Wellington. The accompanying website <http://whiley.org> went live in 2010, making the first versions of Whiley available for download. Since then, Whiley has been in constant development with the majority of contributions being made by the original author. Several scientific papers have published on different aspects of the language, including:

- **Implementing a Language with Flow-Sensitive and Structural Typing on the JVM.** David J. Pearce and James Noble. In *Proceedings of the Workshop on Bytecode Semantics, Verification, Analysis and Transformation (BYTECODE)*, 2011.
- **Sound and Complete Flow Typing with Unions, Intersections and Negations,** David J. Pearce. In *Proceedings of the Conference on Verification, Model Checking and Abstract Interpretation (VMCAI)*, pages 335–354, 2013
- **A Calculus for Constraint-Based Flow Typing.** David J. Pearce. In *Proceedings of the Workshop on Formal Techniques for Java-like Languages (FTFJP)*, Article 7, 2013.
- **Whiley: a Platform for Research in Software Verification.** David J. Pearce and Lindsay Groves. In *Proceedings of the Conference on Software Language Engineering (SLE)*, pages 238–248, 2013
- **Reflections on Verifying Software with Whiley.** David J. Pearce and Lindsay Groves. In *Proceedings of the Workshop on Formal Techniques for Safety-Critical Software (FTSCS)*, 2013

# Chapter 2

## Lexical Structure

This chapter specifies the lexical structure of the Whiley programming language. Programs in Whiley are organised into one or more *source files* written in Unicode. The Whiley language uses *indentation syntax* to delimit blocks and statements, rather than curly-braces (or similar) as found in many other languages.

### 2.1 Line Terminators

A Whiley compiler splits the sequence of (Unicode) input characters into lines by identifying *line terminators*:

```
LineTerminator ::= \n | \r | \r \n
```

Here, \n represents the ASCII character LF (0xA), whilst \r represents the ASCII character CR (0xD). The two characters \r \n taken together form one line terminator.

### 2.2 Indentation

After splitting the input characters into lines, a Whiley compiler then identifies the *indentation* of each line. This is necessary because Whiley employs indentation syntax meaning that indentation is significant in the meaning of Whiley programs.

```
Indentation ::= ^ ( \t |    ) *
```

Here,  $\wedge$  demarcates the start of a line and, hence, indentation may only occur at the beginning of a line. Indentation may be compared using the  $\leq$  comparator, such that  $i \leq ir$  always holds (where  $i$  is some indentation and  $r$  is either empty or represents additional indentation). In other words, some indentation  $i$  is considered less-than-or-equal to another piece of indentation  $ir$  which includes the first as a prefix. This comparator is important for delimiting *statement blocks* (§5.1).

## 2.3 Comments

There are two kinds of comments in Whyley: *line comments* and *block comments*:

```
1 /* This is a block comment */
```

The above illustrates a block comment, which is all of the text between `/*` and `*/` inclusive.

```
1 // This is a line comment
```

The above illustrates a line comment, which is all of the text from `//` up to the end-of-line.

## 2.4 Identifiers

An identifier is a sequence of one or more *letters* or *digits* which starts with a letter.

```
Ident ::= Letter ( Letter | Digit ) *

Letter ::= _ | a | ... | z | A | ... | Z

Digit ::= 0 | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9
```

Letters include lowercase and uppercase alphabetic characters (i.e. `a-z` and `A-Z`) and the underscore (`_`).

## 2.5 Keywords

The following strings are reserved for use as *keywords* and may not be used as identifiers:

```

Keyword ::= all | any | assert | assume | bool | break | byte
          | case | catch | continue | debug
          | default | do | else | ensures | export | false
          | fail | finite | for | function | if | import | in | int
          | is | method | native | new | no | null | package
          | private | protected | public | real | requires
          | return | skip | some | switch | throw
          | throws | total | true | try | void | where | while

```

The following strings are reserved for use as *keywords*, but may additionally be used as identifiers in certain contexts:

```

KeywordIdentifier ::= constant | from | type

```

## 2.6 Literals

A *literal* is a source-level entity which describes a value of primitive type (§4.4).

```

Literal ::= NullLiteral
          | BoolLiteral
          | ByteLiteral
          | IntLiteral
          | RealLiteral
          | CharLiteral
          | StringLiteral

```

### 2.6.1 Null Literal

The `null` type (§4.4.1) has a single value expressed as the `null` literal.

```
NullLiteral ::= null
```

## 2.6.2 Boolean Literals

The **bool** type (§4.4.2) has two values expressed as the `true` and `false` literals.

```
BoolLiteral ::= true | false
```

## 2.6.3 Byte Literals

The **byte** type (§4.4.3) has 256 values which are expressed as sequences of binary digits, followed by the suffix “b” (e.g. `0101b`).

```
ByteLiteral ::= ( 0 | 1 )+ b
```

Byte literals do not need to contain exactly eight digits and, when fewer digits are given, are padded out to eight digits by appending zero’s from the left (e.g. `00101b` becomes `00000101b`).

## 2.6.4 Integer Literals

An *integer literal* is a sequence of numeric or hexadecimal digits (e.g. `123456`, `0xffaf`, etc) corresponding to a value of **int** type (§4.4.4).

```
IntLiteral ::= ( 0 | ... | 9 )+  
              | 0 x ( 0 | ... | 9 | a | ... | f | A | ... | F )+
```

Since integer values in Whiley are of arbitrary size (§4.4.4), there is no limit on the size of an integer literal.

## 2.6.5 Decimal Literals

A *decimal literal* is a sequence of numeric digits separated by a period (e.g. `1.0`, `0.223`, `12.55`, etc) corresponding to a value of **real** type (§4.4.5).

```
RealLiteral ::= ( [0] | ... | [9] )+ [.] ( [0] | ... | [9] )+
```

### 2.6.6 Character Literals

A *character literal* is expressed as a single character or an escape sequence enclosed in single quotes (e.g. `'c'`). Character literals generate integer constants corresponding to Unicode code points, which is necessary because there is no native character type.

```
CharLiteral ::= ['] ( Character | Escape ) [']
```

### 2.6.7 String Literals

A *string literal* is expressed as a sequence of zero or more characters or escape sequences enclosed in double quotes (e.g. `"Hello_World"`). String literals generate lists of integers corresponding to Unicode code points, which is necessary as there is no native string type.

```
StringLiteral ::= [""] ( Character | Escape )* [""]
```

# Chapter 3

## Source Files

Whiley programs are split across one or more source files which are compiled into *WyIL files* prior to execution. Source files contain declarations which describe the functions, methods, data types and constants which form the program. Source files are grouped together into coherent units called *packages*.

### 3.1 Compilation Units

Two kinds of *compilation unit* are taken into consideration when compiling a Whiley source file: other source files; and, binary WyIL files. The Whiley Intermediate Language (WyIL) file format is described elsewhere, but defines a binary representation of a Whiley source file.

```
SourceFile ::= [ PackageDecl ]  
            (  
              | ImportDecl  
              | (Modifier)* TypeDecl  
              | (Modifier)* FunctionDecl  
              | (Modifier)* MethodDecl  
            )*
```

When one or more Whiley source files are compiled together, a *compilation group* is formed. External symbols encountered during compilation are first resolved from the compilation group, and then from previously compiled WyIL files.

### 3.2 Packages

Programs in Whiley are organised into packages to help reduce name conflicts and provide some grouping of related concepts. A Whiley source file may provide an

optional **package** declaration to identify the package it belongs to. This declaration must occur at the beginning of the source file.

```
PackageDecl ::= package Ident ( . Ident )*
```

Any source file which does not provide a **package** declaration is considered to be in the *default package*.

### 3.3 Names

There are four functional entities which can be defined within a Whyley source file: *type declarations* (§3.5.2), *constant declarations* (§3.5.3), *function declarations* (§3.5.4) and *method declarations* (§3.5.5). These define *named entities* which may be referenced from other compilation units. Every named entity has a unique *fully-qualified* name constructed from the enclosing package name, the source file name and the declared name. For example:

Graphics.whyley

```
1 package g2d
2
3 type Point is { int x, int y }
4
5 constant Origin is { x: 0, y: 0 }
```

This declares two entities: `g2d.Graphics.Point` and `g2d.Graphics.Origin`. Two named entities may *clash* if they have the same fully qualified name and are in the same category. There are three entity categories: *types*, *constants* and *functions/methods*. The following illustrates a common pattern:

```
1 type Point is { int x, int y }
2
3 function Point(int x, int y) -> Point:
4     return {x: x, y: y}
```

Here, two named entities share the same fully qualified named. This is permitted because they are in different categories.

Two named entities in the same category with different types are permitted in some circumstances, and is referred to as *overloading*. Currently, overloading is only supported for entities representing function and methods or function and method types.

## 3.4 Imports

When performing *name resolution*, the Whiley compiler first attempts to resolve names within the same source file. For any remaining unresolved, the compiler examines imported entities in reverse declaration order. Entities are imported using an `import` declaration:

```
ImportDecl ::= import [FromSpec] Ident ( [ ] ( Ident | [ ] ) ) *  
  
FromSpec ::= ( Ident | [ ] ) from
```

A declaration of the form “`import a.pkg.File`” imports the compilation unit “`File`” in package “`a.pkg`”. Named entities (e.g. “`Entity`”) within that compilation unit can then be referenced using a *partially qualified* name which omits the package component (e.g. “`File.Entity`”).

A declaration of the form “`import Entity from a.pkg.File`” imports the named entity “`Entity`” from the compilation unit “`File`” residing in package “`a.pkg`”. Note, this does *not* import the compilation unit “`a.pkg.File`” (and, hence, does not subsume the statement “`import a.pkg.File`”).

A *wildcard* may be used in place of the compilation unit name to import *all* compilation units within the given package (e.g. “`import some.pkg.*`”). A *wildcard* may be used in place of the entity name (e.g. “`import * from some.pkg.File`”) to import *all* named entities within the given compilation unit.

## 3.5 Declarations

A *declaration* defines a new entity within a Whiley source file and provides a *name* by which it can be referred to within this source file, or from other source files.

### 3.5.1 Access Control

Several mechanisms for *access control* are provided through *declaration modifiers*.

```
Modifier ::= public | private | native | export
```

- The **public** modifier declares that the declaration is visible from other Whiley source files.
- The **private** modifier declares that the declaration is visible only within the enclosing Whiley source file.

- The **native** modifier declares that the declaration is provided by the underlying system.
- The **export** modifier declares that the declaration is visible to source files written in other languages. Declarations with this modifier cannot be overloaded.

When no modifier is given, the default of **private** is assumed.

**Notes.** The **native** and **export** modifiers together form the *foreign function interface*. The restriction on declarations declared with the **export** modifier is to enable names to be exported without *name mangling*.

### 3.5.2 Type Declarations

A *type declaration* declares a named type within a Whyley source file. The declaration may refer to named types in this or other source files and may also *recursively* refer to itself (either directly or indirectly).

```
TypeDecl ::= type Ident is TypePattern [ where Expr ]
```

The optional **where** clause defines a *boolean expression* which holds for any instance of this type. This is often referred to as the type *invariant* or *constraint*. Variables declared within the *type pattern* may be referred to within the optional **where** clause.

All types are required to be *contractive*. This means, for example, that the declaration **type** *x* **is** *x* is considered invalid.

**Examples.** Some simple examples illustrating type declarations are:

```
1 // Define a simple point type
2 type Point is { int x, int y }
3
4 // Define the type of natural numbers
5 type nat is (int x) where x >= 0
```

The first declaration defines an unconstrained record type named `Point`, whilst the second defines a constrained integer type `nat`.

**Notes.** A convention is that type declarations for *records* or *unions of records* begin with an upper case character (e.g. `Point` above). All other type declarations begin with lower case. This reflects the fact that records are most commonly used to describe objects in the domain.

### 3.5.3 Constant Declarations

A *constant declaration* declares a named constant within a Whiley source file. The declaration may refer to named constants in this or other source files, although it may not refer to itself (either directly or indirectly).

```
ConstantDecl ::= constant Ident is Expr
```

The given *constant expression* is evaluated at *compile time* and must produce a constant value. This prohibits the use of function or method calls within the constant expression. However, general operators (e.g. for arithmetic) are permitted.

**Examples.** Some simple examples to illustrate constant declarations are:

```
1 // Define the well-known mathematical constant to 10 decimal places.
2 constant PI is 3.141592654
3
4 // Define a constant expression which is twice PI
5 constant TWO_PI is PI * 2.0
```

The first declaration defines the constant `PI` to have the **real** value `3.141592654`. The second declaration illustrates a more interesting constant expression which is evaluated to `6.283185308` at compile time.

**Notes.** A convention is that constants are named in upper case with underscores separating words (i.e. as in `TWO_PI` above).

### 3.5.4 Function Declarations

A *function declaration* defines a function within a Whiley source file. Functions are *pure* and may not have side-effects. This means they are guaranteed to return the same result given the same arguments, and are permitted within specifications (i.e. in type invariants, *loop invariants*, and function/method *preconditions* or *postconditions*). Functions may call other functions, but may not call other methods. Functions may not explicitly allocate memory on the heap and/or instigate concurrent computation.

```
FunctionDecl ::= function Ident TypePattern -> TypePattern (
    requires Expr | ensures Expr
)* : Block
```

The first type pattern (i.e. before “->”) is referred to as the *parameter*, whilst the second is referred to as the *return*. There are three kinds of optional clause which follow:

- **Requires clause(s).** These define constraints on the permissible values of the parameters on entry to the function, and are often collectively referred to as the precondition. These expressions may refer to any variables declared within the parameter type pattern. Multiple clauses may be given, and these are taken together as a conjunction. The convention is to specify the **requires** clause(s) before any **ensures** clause(s).
- **Ensures clause(s).** These define constraints on the permissible values of the function’s return value, and are often collectively referred to as the postcondition. These expressions may refer to any variables declared within either the parameter or return type pattern. Multiple clauses may be given, and these are taken together as a conjunction. The convention is to specify **ensures** clause(s) after **requires** clause(s).

**Examples.** The following function declaration provides a small example to illustrate:

```
1 function max(int x, int y) -> (int z)
2 // return must be greater than either parameter
3 ensures x <= z && y <= z
4 // return must equal one of the parameters
5 ensures x == z || y == z:
6     // implementation
7     if x > y:
8         return x
9     else:
10        return y
```

This defines the specification and implementation of the well-known `max()` function which returns the largest of its parameters. This does not enforce any preconditions on its parameters.

### 3.5.5 Method Declarations

A *method declaration* defines a method within a Whyley source file. Methods are *impure* and may have side-effects. Thus, they cannot be used within specifications (i.e. in type invariants, loop invariants, and function/method preconditions or postconditions). However, unlike functions, methods may call other functions and/or methods (including **native** methods). They may also explicitly allocate memory on the heap, and/or instigate concurrent computation.

```

MethodDecl ::= method Ident TypePattern -> TypePattern (
               requires Expr | ensures Expr
            )* : Block

```

The first type pattern (i.e. before “->”) is referred to as the *parameter*, whilst the second is referred to as the *return*. The three optional clauses are defined identically as for function declarations (§3.5.4).

**Examples.** The following method declaration provides a small example to illustrate:

```

1 // Define the well-known concept of a linked list
2 type LinkedList is null | &{ LinkedList next, int data }
3
4 // Define a method which inserts a new item onto the end of the list
5 method insertAfter(LinkedList list, int item) -> LinkedList:
6     if list is null:
7         // reached the end of the list, so allocate new node
8         return new { next: null, data: item }
9     else:
10        // continue traversing the list
11        list->next = insertAfter(list->next, item)
12    return list

```

# Chapter 4

## Types & Values

The Whiley programming language is *statically typed*, meaning that every expression has a type determined at compile time. Furthermore, evaluating an expression is guaranteed to yield a value of its type. Whiley’s *type system* governs how the type of any variable or expression is determined. Whiley’s type system is unusual in that it incorporates *union types* (§4.11), *intersection types* (§4.12) and *negation types* (§4.13), as well as employing *flow typing* and *structural typing*.

### 4.1 Overview

Types in Whiley are unusual (in part) because there is a large gap between their *syntactic* description and their underlying *semantic* meaning. In most programming languages (e.g. Java), this gap is either small or non-existent and, hence, there is little to worry about. However, in Whiley, we must tread carefully to avoid confusion. The following example attempts to illustrate this gap between the syntax and semantics of types:

```
1  function id(null|int x) -> int|null:  
2      return x
```

In this function we see two distinct *type descriptors* expressed in the program text, namely “`int|null`” and “`null|int`”. Type descriptors occur at the source-level and describe *types* which occur at the semantic level. In this case, we have two distinct type descriptors which describe the *same* underlying semantic type. We will often refer to types as providing the semantic (i.e. meaning) of type descriptors.

## 4.2 Type Descriptors

Type descriptors provide syntax for describing types and, in the remaining sections of this chapter, we explore the range of types supported in Whyley. The top-level grammar for type descriptors is:

```
Type ::= UnitType ( [ , ] UnitType ) *

UnitType ::= UnionType
           | IntersectionType
           | TermType

TermType ::=
           | PrimitiveType
           | RecordType
           | ReferenceType
           | NominalType
           | ArrayType
           | NegationType
           | FunctionType
           | MethodType
           | ( [ Type ] )
```

## 4.3 Type Patterns

*Type patterns* associate variables with types and their subcomponents and can be used to declare variables and/or for *destructuring* types into variables. Type patterns are a source-level entity which are similar to type descriptors. The top-level grammar for type patterns is:

```
TypePattern ::= Type [ Ident ]
              | TuplePattern
              | RecordPattern
              | RationalPattern
```

## 4.4 Primitive Types

Primitive types are the atomic building blocks of all types in Whyley.

```
PrimitiveType ::=
    | AnyType
    | VoidType
    | NullType
    | BoolType
    | ByteType
    | IntType
    | RealType
```

### 4.4.1 Null

The null type is typically used to show the absence of something. It is distinct from void, since variables can hold the special `null` value (where as there is no special “`void`” value). The set of values defined by the type `null` is the singleton set containing exactly the `null` value. Variables of `null` type support only equality comparators (§6.7). The `null` value is particularly useful for representing optional values and terminating recursive types.

```
NullType ::= null
```

**Example.** The following illustrates a simple example of the `null` type:

```
1  type Tree is null | { int data, Tree left, Tree right }
2
3  function height(Tree t) -> int:
4      if t is null:
5          // height of empty tree is zero
6          return 0
7      else:
8          // height is this node plus maximum height of subtrees
9          return 1 + Math.max(height(t.left), height(t.right))
```

This defines `Tree` — a *recursive type* — which is either empty (i.e. `null`) or consists of a field `data` and two subtrees, `left` and `right`. The `height` function calculates the height of a `Tree` as the longest path from the root through the tree.

**Notes.** With all of the problems surrounding `null` and `NullPointerExceptions` in languages like Java and C, it may seem that this type should be avoided. However, it remains a very useful abstraction (e.g. for terminating recursive types) and, in Whiley, is treated in a completely safe manner (unlike e.g. Java).

## 4.4.2 Booleans

The **bool** type represents the set of boolean values (i.e. `true` and `false`). Variables of **bool** type support equality comparators (§6.7), binary logical operators (§6.10) and logical not (§6.10.1).

```
BoolType ::= bool
```

**Example.** The following illustrates a simple example of the **bool** type:

```
1 // Determine whether item is contained in list or not
2 function contains([int] list, int item) -> bool:
3     // examine every element of list
4     int i = 0
5     while i < |list|:
6         if l == item:
7             return true
8         i = i + 1
9     // done
10    return false
```

This function determines whether or not a given integer value is contained within an array of integers. If so, it returns `true`, otherwise it returns `false`.

## 4.4.3 Bytes

The type **byte** represents the set of eight-bit sequences, whose values are expressed numerically using 0 and 1 followed by `b` (e.g. `00101b`). The set of values defined by the **byte** type is the set of all 256 possible combinations of eight-bit sequences. Variables of **byte** type support equality comparators (§6.7), bitwise operators (§6.5), bitwise complement (§6.5.1) and shift operators (§6.5.3).

```
ByteType ::= byte
```

**Example.** The following illustrates a simple example of the **byte** type:

```
1 // convert a byte into a string
2 function toString(byte b) -> ASCII.string:
3     ASCII.string r = "b"
4     int i = 0
5     while i < 8:
```

```

6      if (b & 00000001b) == 00000001b:
7          r = "1" ++ r
8      else:
9          r = "0" ++ r
10         b = b >> 1
11         i = i + 1
12     return r

```

This illustrates the conversion from a **byte** into a **string**. The conversion is performed one digit at a time, starting from the rightmost bit.

**Notes.** Unlike for many languages, there is no representation associated with a byte. For example, to extract an integer value from a byte, it must be explicitly decoded according to some representation (e.g. two's complement) using an auxillary function (e.g. `Byte.toInt()`).

#### 4.4.4 Integers

The type **int** represents the set of arbitrary-sized integers, whose values are expressed as a sequence of one or more numerical or hexadecimal digits (e.g. 123456, 0xffaf, etc). Variables of **int** type support equality comparators (§6.7), inequality comparators (§??), additive (§6.4.3), multiplicative (§6.4.4) and negation (§6.4.1) operations.

```
IntType ::= int
```

**Example.** The following illustrates a simple example of the **int** type:

```

1  function fib(int x) -> int:
2      if x <= 1:
3          return x
4      else:
5          return fib(x-1) + fib(x-2)

```

This illustrates the well-known recursive method for computing numbers in the *fibonacci* sequence.

**Notes.** Since integers in Whiley are of arbitrary size, *integer overflow* is not possible. This contrasts with other languages (e.g. Java) that used *fixed-width* number representations (e.g. 32bit two's complement). Furthermore, there is nothing equivalent to the constants found in such languages for representing the uppermost and least integers expressible (e.g. `Integer.MIN_VALUE` and `Integer.MAX_VALUE`, as found in Java).

## 4.4.5 Rationals

The type **real** represents the set of arbitrary-sized rationals, whose values are expressed as a sequence of one or more numerical digits separated by a period (e.g. 1.0, 0.223, 12.55, etc). The set of values defined by the type **real** is the (infinite) set of all integer pairs, where the first element is designated the numerator, and the second designated the denominator. Variables of **real** type support equality comparators (§6.7), inequality comparators (§??), additive (§6.4.3), multiplicative (§6.4.4) and negation (§6.4.1) operations. Variables of type **real** also support the *rational destructuring assignment* to extract the numerator and denominator (illustrated below).

```
RealType ::= real
```

**Example.** The following illustrates a simple example of the **real** type:

```
1 function floor(real x) -> int:
2     int num / int den = x      // extract numerator and denominator
3     int r = num / den         // integer division
4     if x < 0.0 && den != 1:
5         return r - 1
6     else:
7         return r
```

This illustrates the well-known function for computing the *floor* of a **real** variable  $x$  (i.e. the greatest integer not larger than  $x$ ). The rational destructuring assignment is used to extract the numerator and denominator of the parameter  $x$ .

## 4.4.6 Any

The type **any** represents the type whose variables may hold any possible value. Thus, **any** is the *top type* (i.e.  $\top$ ) in the lattice of types and, hence, is the supertype of all other types. Variables of **any** type support equality comparators (§6.7) and type tests (§??).

```
AnyType ::= any
```

**Example.** The following illustrates a simple example of the **any** type:

```
1 function toInt(any val) -> int:
2     if val is int:
3         return val
4     else if val is real:
```

```

5      return Math.floor(val)
6  else:
7      return 0 // default value

```

Here, the function `toInt` accepts *any valid Whyley value*, which includes all values of type **int**, **real**, collections, records, etc. The function then inspects the value that it has been passed and, in the case of values of type **int** and **real**, returns an integer approximation; for all other values, it returns 0.

**Notes.** The any type is roughly comparable to the `Object` type found in pure object-oriented languages. However, in impure object-oriented languages which support primitive types, such as Java, this comparison often falls short because `Object` is not a supertype of primitives such as **int** or `long`.

## 4.4.7 Void

The **void** type represents the type whose variables cannot exist (i.e. because they cannot hold any possible value). Thus, **void** is the *bottom type* (i.e.  $\perp$ ) in the lattice of types and, hence, is the *subtype* of all other types. Void is used to represent the return type of a method which does not return anything. Furthermore, it is also used to represent the element type of an empty array. Finally, unlike the majority of other types, there are no *values* of type **void**.

```
VoidType ::= void
```

**Example.** The following example illustrates several uses of the **void** type:

```

1  // Attempt to update first element
2  method update1st(&[int] list, int value) -> void:
3      // First, check whether list is empty or not
4      if (*list) != []:
5          // Then, update 1st element
6          (*list)[0] = value
7      // done

```

Here, the method `update1st` is declared to return **void** — meaning it does not return a value. Instead, this method updates some existing state accessible through the reference `list`. Within the method body, the value accessible via this reference is compared against `[]` (i.e. the *empty array*).

## 4.5 Tuples

A tuple type describes a compound type made up of two or more elements in sequence, whose values are expressed as sequences of values separated by a comma (e.g. `1, 2, 2.0, 3.32, 3.45`, etc). Tuples are similar to records, except that fields are effectively anonymous. Variables of tuple type support equality comparators (§6.7), as well the *tuple destructuring assignment* to extract elements (illustrated below).

$$\begin{aligned}\text{TupleType} &::= ( \text{Type} ( , \text{Type} )^+ ) \\ \text{TuplePattern} &::= ( \text{TypePattern} ( , \text{TypePattern} )^+ ) [ \text{Ident} ]\end{aligned}$$

**Example.** The following example illustrates several uses of tuples:

```
1 function swap(int x, int y) -> (int,int):  
2   return y, x
```

This function accepts two integer parameters, and returns a tuple type containing two integers. The function reverses the order that the values occur in the tuple passed as a parameter.

## 4.6 Records

A record type describes a compound made of one or more *fields*, each of which has a unique name and a corresponding type. Variables of record type support equality comparators (§6.7) and field access (§??) operations, as well as field assignment (§??).

$$\text{RecordType} ::= \{ \text{MixedType} ( , \text{MixedType} )^* [ , \dots ] \}$$

Records use *mixed types* for defining fields (see §??), meaning that field names may be mixed within their type. This is primarily useful for fields of function or method type (see below). Records using the `...` notation are referred to as *open records* (e.g. `{int x, ...}`), otherwise they are referred to as *closed records* (e.g. `{int x, int y}`). Open records represent all records containing *at least* the given fields, whilst closed records represent those containing *exactly* the given fields.

**Example.** The following example illustrates an open record type:

```

1  type Writer is {
2      method write([byte]) -> int,
3      ...
4  }
5  type PrintWriter is {
6      method write([byte]) -> int,
7      method println(ASCII.string) -> void,
8      ...
9  }

```

The above illustrates two open records `Writer` and `PrintWriter`. The former has one field (`write`), whilst the latter has two fields (`write` and `println`). The above also illustrates use of mixed types. For example, the field “`write`” is declared as “`method write([byte]) -> int`” which mixes together the field name (i.e. “`write`”) with its type (i.e. “`method([byte]) -> int`”).

## 4.7 References

Reference types in Whyley represent references to variables, such as those allocated in the heap. They are similar to references or pointers found in many imperative and object-oriented languages (e.g. C/C++, Java, C#, etc). A type `&T` represents a reference to a variable of type `T`. Variables of reference type support equality comparators (§6.7) and dereference (§6.13.2) operations, as well as dereference assignment (§??).

ReferenceType ::= `&` Type

**Example.** The following example illustrates reference types:

```

1  // Swap contents of heap-allocated int variables
2  method swap(&int pX, &int pY):
3      int tmp = *pX
4      *pX = *pY
5      *pY = tmp

```

The above illustrates a method which accepts two references to variables of type `int` that may refer to the same variable. The method simply swaps the contents of the variables to which they refer.

## 4.8 Nominals

Nominal types represent user-defined types declared within one or more Whiley source files. Nominal types provide a mechanism for enforcing *information hiding*, and also for constructing *recursive types* (§4.14). All nominal types have an underlying — or, *concrete* — type and are indistinguishable from this type.

```
NominalType ::= Ident
```

**Example.** The following example illustrates nominal types:

```
1 // Using a nominal type to construct a recursive type
2 type LinkedList is null | { int data, LinkedList next }
```

The type `LinkedList` is declared using a reference to itself to define a recursive type (§4.14).

## 4.9 Arrays

An array type describes an array of values whose elements are subtypes of the element type. For example, `[1, 2, 3]` is an instance of array type `int[]`; however, `[1.345]` is not. Variables of array type support equality comparators (§6.7) and access expressions (§6.11.2).

```
ArrayType ::= Type [ ]
```

**Example.** The following example illustrates array types:

```
1 function add([int] v1, [int] v2) -> ([int] v3)
2 requires |v1| == |v2|
3 ensures |v1| == |v3|:
4     //
5     int i=0
6     while i < |v1|:
7         v1[i] = v1[i] + v2[i]
8         i = i + 1
9     return v1
```

The above illustrates a simple function which adds each corresponding element from two integer array together. The function's precondition requires that both input

arrays have the same length, whilst its postconditions ensures that this matches the length of the output.

## 4.10 Functions and Methods

A function or method type describes the signature of a function or method. These types enable functions or methods to be passed around as values in Whiley and are often referred to as *functors*. This enables a degree of polymorphism in the language, where the exact function or method to be called is unknown. Variables of function or method type support equality comparators (§6.7) only.

```
FunctionType ::= function ( [ Type ( , Type )* ] ) -> UnitType

MethodType ::= method ( [ Type ( , Type )* ] ) -> UnitType
```

**Example.** The following example illustrates function types:

```
1  type Fun is function(int) -> int
2
3  function map([int] items, Fun fn) -> [int]:
4      //
5      int i = 0
6      while i < |items|:
7          items[i] = fn(items[i])
8          i = i + 1
9      //
10     return items
```

The above illustrates the well-known *map* function, which maps all elements of an array according to a given function.

## 4.11 Unions

A union type is constructed from two or more component types and contains any value held in any of its components. For example, the type `null | int` is a union which holds either an integer value or `null`. The set of values defined by a union type `T1 | T2` is exactly the union of the sets defined by `T1` and `T2`. In general, variables of union type support only equality comparators (§6.7) and type tests (§7.7). See §4.15 for exceptions to this.

```
UnionType ::= IntersectionType ( | IntersectionType )*
```

**Example.** The following example illustrates a union type:

```
1 // Return lowest index of matching item, or null if none
2 function indexOf([int] items, int value) -> int|null:
3     int i = 0
4     while i < |items|:
5         if items[i] == value:
6             // match
7             return i
8         i = i + 1
9     // item not found
10    return null
```

Here, a union type is used to construct a more expressive return value. If no matching element is found, `null` is returned (rather than e.g. `-1`).

## 4.12 Intersections

An intersection type is constructed from two or more component types and contains any value held in all of its components. For example, the type `[int] & [bool]` is an intersection which holds any value which is both an instance of `[int]` and `[bool]` (in fact, only the empty array meets this criteria). Intersections are used, for example, to type variables on the true branch of a runtime type test. The set of values defined by an intersection type `T1 & T2` is exactly the intersection of the sets defined by `T1` and `T2`. In general, variables of intersection type support only equality comparators (§6.7) and type tests (§??). See §4.15 for exceptions to this.

```
IntersectionType ::= TermType ( & TermType )*
```

**Example.** The following example illustrates an intersection type:

```
1 type Reader is {
2     method read(int) -> [byte],
3     ...
4 }
5 type Writer is {
6     method write([byte]) -> int,
```

```

7   ...
8   }
9   type ReaderWriter is Reader & Writer

```

Here, the type `Reader` is defined as any record containing a `read(int)` method, whilst the type `Writer` is defined as any record containing a `write([byte])` method. Then, the intersection type `ReaderWriter` is defined as any record containing *both* a `read(int)` and `write([byte])` method.

## 4.13 Negations

A negation type is constructed from a component type and contains any value *not* held in its component. For example, the type `!int` is a negation which holds any non-integer value. Negations are used, for example, to type variables on the false branch of a runtime type test. The set of values defined by a negation type `!T1` is exactly the set of all values less those defined by `T1`. In general, variables of negation type support only equality comparators (§6.7) and type tests (§7.7). See §4.15 for exceptions to this.

```
NegationType ::= ! TermType
```

**Example.** The following example illustrates a negation type:

```

1  function f(any item) -> !null:
2      if item is null:
3          return 0
4      else:
5          return item

```

Here, the function `f()` accepts a parameter of any type, and returns a value which is permitted to be anything except `null`. The above also illustrates how the type test operator retypes variables on the false branch using negation types.

## 4.14 Recursive Types

Recursive types describe tree-like structures of arbitrary depth. For example, linked lists, binary trees, quad trees, etc can all be described using recursive types. Recursive types have no explicit syntax and, instead, are declared indirectly in terms of themselves using one or more nominal types (§4.8).

**Example.** The following example illustrates a simple recursive type:

```
1  type Node is { Tree left, Tree right, int data }
2  type Tree is null | Node
3
4  function sizeOf(Tree t) -> int:
5      if t == null:
6          return 0
7      else:
8          return 1 + sizeOf(t.left) + sizeOf(t.right)
```

Here, the type `Tree` is recursive because it is defined in terms of itself. An instance of type `Tree` is a sequence of nested records which is arbitrarily deep, and whose branches are terminated by `null`. The function `sizeOf()` traverses an arbitrary instance of `Tree` and returns the number of `Nodes` it contains.

## 4.15 Effective Types

An effective type is a union of types which all contain some property (e.g. a union of arrays). This common property allows the effective type to support more operations than possible for an arbitrary union (§4.11).

### 4.15.1 Effective Tuples

An effective tuple is a union of two or more tuple types. For example, the type `(int, int) | (real, real)` is an effective tuple. An effective tuple type supports all operations valid for a tuple type (§4.5).

### 4.15.2 Effective Records

An effective record is a union of two or more record types with at least one field in common. For example, `{int f, int g} | {real f, int h}` is an effective record. An effective record provides access to fields common to all records in the union. For example, the type `{int f, int g} | {real f, int h}` can be viewed as having an effective type of `{int|real f, ...}` and, hence, read access to field `f` is given.

### 4.15.3 Effective Array

An effective array is a union of array types. For example, `int[] | real[]` is an effective array. An effective collection supports all operations valid for a array type (§4.9). For example, the type `int[] | real[]` can be viewed as having an effective type of `(int|real) []` and, hence, read access to its length and elements is given.

## 4.16 Semantics

Although types are abstract entities we can (for the most part) imagine them as describing sets of *abstract values*. For example, `int | null` denotes the set of values containing exactly the (infinite) set of integers and `null` (i.e.  $\mathbb{Z} \cup \{\text{null}\}$ ). This is often referred to as a set-theoretic interpretation of types<sup>[15;16;17;18]</sup>. Under this interpretation, for example, one type *subtypes* another if the set of values it denotes is a *subset* of the other (see § 4.16.2 for more).

### 4.16.1 Equivalences

Since types are defined in terms of the set of values they represent, it is possible for two distinct type descriptors to describe the same underlying type. For example, `int | null` is considered equivalent to `null | int`. Whilst this case is fairly easy to spot, others are not so obvious. Some examples are given here to illustrate:

- `!any` is equivalent to `void` and, conversely, `any` is equivalent to `!void`
- `int & !int` is equivalent to `void` and, conversely, `int | !int` is equivalent to `any`
- `{int | null f}` is equivalent to `{int f} | {null f}`
- `{int | null f} & {bool | null f}` is equivalent to `{null f}`

Unfortunately, an infinite number of equivalences exist between the type descriptors of Whiley, and we cannot list them all here.

### 4.16.2 Subtyping

Types in Whiley support the notion of *subtyping* where one type may be a *subtype* for another. For example, the type `int` is a subtype of `any`. Likewise, `bool` is a subtype of `bool | null`. The *subtyping operator* is denoted by “ $\leq$ ”; for example,  $T_1 \leq T_2$  indicates that type  $T_1$  is a subtype of  $T_2$ . The subtyping operator is *reflexive*, *transitive* and *anti-symmetric* with respect to the underlying types involved.

The subtyping operator is regarded as an algorithm for determining whether the type described by one type descriptor is a subtype of another. The implementation of this algorithm is not straightforward and a full discussion of it is beyond the scope of this document. Indeed, there are many possible implementations of this operator.

# Chapter 5

## Statements

The execution of a Whiley program is controlled by *statements*, which cause effects on the environment. However, statements in Whiley do not produce values. *Compound statements* may contain other statements.

### 5.1 Blocks

A statement block is a sequence of zero or more consecutive statements which have the same indentation (§2.2). Statement blocks are used to group statements together when constructing compound statements. For example:

```
1  function sum([int] items) -> int:  
2      // outer block begins  
3      int r = 0  
4      int i = 0  
5      while i < |items|:  
6          // inner block begins  
7              r = r + items[i]  
8              i = i + 1  
9          // inner block ends  
10     //  
11     return r  
12     // outer block ends
```

The above example contains two statement blocks, one nested inside the other. The outer block demarcates the body of the `sum()` function, whilst the inner block demarcates the body of the `while` statement.

## 5.2 Simple Statements

A *simple statement* is a statement where control always continues to the next statement in sequence. Simple statements do not contain other statements nested within them.

### 5.2.1 Assert Statement

An *assert statement* is of the form “**assert** *e*”, where *e* is a boolean expression. A *fault* will be raised at runtime if the asserted expression evaluates to *false*; otherwise, execution will proceed normally. At verification time, the verifier is forced to ensure that the asserted expression is true for all possible execution paths. This allows the programmer to specify and check something he/she believes to be true at a given point in the program.

```
AssertStmt ::= assert Expr
```

**Example.** The following illustrates an **assert** statement:

```
1 function abs(int x) -> int:  
2   if x < 0:  
3     x = -x  
4   assert x >= 0  
5   return x
```

Here, an assertion is used to check that the value being returned by the `abs()` is non-negative. Since this is a true statement of the function, this statement will never raise a fault.

### 5.2.2 Assignment Statement

An *assignment statement* is of the form `leftHandSide = rightHandSide`. Here, the `rightHandSide` is any expression, whilst the `leftHandSide` must be an `LVal` — that is, an expression permitted on the left-hand side of an assignment. At runtime, the value generated by evaluating the right-hand side must be a subtype (§4.16.2) of the left-hand side.

```
AssignStmt ::= LVal = Expr
```

**Example.** The following illustrates different possible assignment statements:

```
1  method f1([int] x, [int] y):  
2      x = y           // variable assignment  
3  
4  method f2({int f} x, int y):  
5      x.f = y         // field assignment  
6  
7  method f3([int] x, int i, int y):  
8      x[i] = y        // list assignment  
9  
10 method f4([int f] x, int i, int y):  
11     x[i].f = y       // compound assignment
```

The last assignment here illustrates that the left-hand side of an assignment can be arbitrarily complex, involving nested assignments into arrays and records.

### 5.2.3 Assume Statement

An *assume statement* is of the form “**assume** *e*”, where *e* is a boolean expression. A fault will be raised at runtime if the assumed expression evaluates to `false`; otherwise, execution will proceed normally. At verification time, the verifier will automatically assume that the given expression holds. Thus, **assume** statements provide a way for the programmer to override the verifier. This is useful where the verifier is unable to establish something that the programmer knows to be true. Care must be taken to ensure that the assumed expression really does hold.

```
AssumeStmt ::= assume Expr
```

**Example.** The following illustrates an **assume** statement:

```
1  function abs(int x) -> (int y) ensures y >= 0:  
2      //  
3      assume x >= 0  
4      return x
```

Here, the programmer has used an assumption to ensure this function passes verification. This would not appear to be safe in this case, and may lead to a fault at runtime.

### 5.2.4 Debug Statement

A *debug statement* outputs the result of evaluating its expression to the *debug stream*. Debug statements are intended to be used purely for debugging, particularly from

within (pure) functions. The debug stream is an imaginary output stream which does not exist in the true semantic of the language. Instead, from an operational semantics perspective, the debug statement is equivalent to the skip statement (§5.2.5).

```
DebugStmt ::= debug Expr
```

**Example.** The following illustrates a debug statement:

```
1 function f(int x) -> int:
2   debug "f(int)_called"
3   if x == 1 || x == 0:
4     return x
5   else:
6     return f(x-1) + f(x-2)
```

Here, we see a recursive implementation of the well-known *fibonacci* sequence. A debug statement is being used to report when a given function is invoked.

## 5.2.5 Skip Statement

A *skip statement* is a no-operation and has no effect on the environment. This statement can be useful for representing empty statement blocks (§5.1).

```
SkipStmt ::= skip
```

**Example.** The following illustrates a **skip** statement:

```
1 function abs(int x) -> (int y)
2 // Return value cannot be negative
3 ensures y >= 0:
4   //
5   if x >= 0:
6     skip
7   else:
8     x = -x
9   //
10  return x
```

Here, we see a **skip** statement being used to represent an empty statement block.

## 5.2.6 Variable Declaration Statement

A *variable declaration* statement has an optional expression assignment referred to as a *variable initialiser*. If an initialiser is given, this will be evaluated and assigned to the declared variables when the declaration is executed.

```
VarDecl ::= TypePattern [ = Expr ]
```

**Example.** Some example variable declarations are:

```
1 method f():
2     int x
3     int y = 1
4     int z = y + y
5     int a, int b = y, z
```

Here we see four variable declarations. The first has no initialiser, whilst the remainder have initialisers. The final declaration illustrates a more complex use of type patterns where two variables of type `int` are initialised from a tuple expression

## 5.3 Control Statements

A *control statement* is a statement which may have multiple exit points, and where control does not always continue to the next statement in sequence. Control statements may contain other statements nested within them.

### 5.3.1 Break Statement

A *break statement* transfers control out of the lexically-nearest enclosing loop (i.e. `do`, `while`). It is a compile-time error if no such enclosing loop exists.

```
BreakStmt ::= break
```

**Example.** The following illustrates a `break` statement:

```
1 // Remove lowest element holding x from xs
2 function remove([int] xs, int x) -> [int]:
3     int i = 0
4     while i < |xs|:
5         if xs[i] == x:
```

```

6      break
7      else:
8          i = i + 1
9      return xs[0..i] ++ xs[i+1..]

```

Here, we see a **break** statement being used to exit a **while** loop when the first element matching parameter  $x$  is found.

**Notes.** Unlike many other programming languages (e.g. Java), **break** statements cannot be used to transfer control out of a **switch** statement (§5.3.7). This is because **switch** statements have *explicit*, rather than *implicit*, fall-through.

### 5.3.2 Continue Statement

A *continue statement* can be used either to transfer control to the next iteration of the enclosing loop (i.e. **do**, **while**), or to transfer control to the next case of the enclosing **switch** statement.

```
ContinueStmt ::= continue
```

**Example.** The following illustrates a **continue** statement:

```

1  function sumNonNegative([int] xs) -> int:
2      int i = 0
3      int r = 0
4      while i < |xs|:
5          if xs[i] < 0:
6              continue
7          r = r + xs[i]
8          i = i + 1
9      return r

```

Here, a **continue** statement is used to ensure that negative numbers are not included in the result of the function.

**Notes.** Unlike many other programming languages (e.g. Java), **continue** statements are used to transfer control to the next case of a **switch** statement (§5.3.7). This is because **switch** statements have *explicit*, rather than *implicit*, fall-through.

### 5.3.3 Do/While Statement

A do-while statement repeatedly executes a statement block until an expression (the condition) evaluates to `false`. Optional **where** clause(s) are permitted which, together, are commonly referred to as the loop invariant.

$$\text{DoWhileStmt}^\ell ::= \boxed{\text{do}} \boxed{:} \text{Block}^\gamma \boxed{\text{while}} \text{Expr} ( \boxed{\text{where}} \text{Expr} )^*$$

(where  $\ell < \gamma$ )

**Example.** The following illustrates an do-while statement:

```
1 function sum([int] xs) -> int
2 // Input must not be empty list
3 requires |xs| > 0:
4 //
5 int r = 0
6 int i = 0
7 do:
8     r = r + xs[i]
9     i = i + 1
10 while i < |xs| where i >= 0
11 //
12 return r
```

Here, we see a simple do-while statement which sums the elements of variable `xs`, storing the result in variable `r`. A loop invariant is given which establishes that variable `i` is non-negative.

**Notes.** When multiple **where** clauses are given, these are combined using a conjunction to form the loop invariant. The combined invariant must hold after each iteration. Thus, when the condition evaluates to `false`, the loop invariant is guaranteed to hold. However, the loop invariant need not hold when the loop is exited using a **break** (§5.3.1) statement.

### 5.3.4 Fail Statement

A *fail statement* is used to signal unreachable code. At runtime, this forces abrupt termination of the program. At verification time, the verifier will ensure the statement is unreachable.

```
FailStmt ::= fail
```

**Example.** The following illustrates a `fail` statement:

```
1 type nat is (int x) where x >= 0
2 type neg is (int x) where x < 0
3
4 function f(int|null x) -> bool|null:
5 //
6   if x is nat:
7     return true
8   else if x is neg:
9     return false
10  else:
11    fail
```

Here, we see a simple function which checks whether its parameter `x` is positive or negative. A `fail` statement is used to signal that the last branch is, in fact, unreachable.

### 5.3.5 If Statement

An `if` statement conditionally executes a statement block based on the outcome of one or more expressions. Chaining of `if` statements is permitted, and an optional `else` branch may be given. The expression(s) are referred to as *conditions* and must be boolean expressions. The first block is referred to as the *true branch*, whilst the optional `else` block is referred to as the *false branch*.

$$\text{IfStmt}^\ell ::= \boxed{\text{if}} \text{Expr} \boxed{:} \text{Block}^\gamma \left( \boxed{\text{else}} \boxed{\text{if}} \text{Expr} \boxed{:} \text{Block}^{\omega_i} \right)^* \\ \left[ \boxed{\text{else}} \boxed{:} \text{Block}^\phi \right]$$

(where  $\ell < \gamma$  and  $\forall i. \ell < \omega_i$  and  $\ell < \phi$ )

**Example.** The following illustrates an `if` statement:

```
1 function max(int x, int y) -> int:
2   if(x > y):
3     return x
4   else if(x == y):
5     return 0
6   else:
```

```
return y
```

Here, we see an **if** statement with two conditional outcomes and one default outcome.

### 5.3.6 Return Statement

A *return statement* has an optional expression referred to as the *return value*. At run-time, this statement returns control to the caller of the enclosing function or method. At verification time, the verifier will ensure the returned value meets the postcondition of the enclosing function or method.

```
ReturnStmt ::= return [ Expr ]
```

**Example.** The following illustrates a **return** statement:

```
1 function f(int x) -> int:
2   return x + 1
```

Here, we see a simple function which returns the increment of its parameter  $x$  using a **return** statement.

**Notes.** The returned expression (if there is one) must begin on the same line as the statement itself.

### 5.3.7 Switch Statement

A *switch statement* transfers control to one of several statement blocks, referred to as *switch cases*, depending on the value obtained from evaluating a given expression. Each case is associated with one or more values which are used to match against. If no match is made, control either falls through to the next statement following the **switch** or is transferred to a **default** block if one is given.

```
SwitchStmtℓ ::= switch Expr : ( CaseBlockγ | DefaultBlockγ )+
```

```
CaseBlockℓ ::= case ConstantExpr ( , ConstantExpr )* : Blockγ
```

```
DefaultBlockℓ ::= default : Blockγ
```

(where  $\ell < \gamma$ )

**Example.** The following illustrates a **switch** statement:

```
1  function toDescriptorString(Primitive t) -> string:
2      switch t:
3          case Boolean:
4              return "Z"
5          case Byte:
6              return "B"
7          case Char:
8              return "C"
9          case Short:
10             return "S"
11          case Int:
12             return "I"
13          case Long:
14             return "J"
15          case Float:
16             return "F"
17          default:
18             return "D"
```

Here, we see a simple **switch** statement which choose between a number of possible values of type `Primitive`. A **default** case is given which catches the only remaining case (i.e. representing the value `Double`).

### 5.3.8 While Statement

A while statement repeatedly executes a statement block until an expression (the condition) evaluates to `false`. Optional **where** clause(s) are permitted which, together, are commonly referred to as the loop invariant.

$$\text{WhileStmt}^\ell ::= \boxed{\text{while}} \text{ Expr } ( \boxed{\text{where}} \text{ Expr } )^* \boxed{:} \text{Block}^\gamma$$

(where  $\ell < \gamma$ )

**Example.** The following illustrates an **while** statement:

```
1  function sum([int] xs) -> int:
2      int r = 0
3      int i = 0
4      while i < |xs| where i >= 0:
5          r = r + xs[i]
6          i = i + 1
7      return r
```

---

Here, we see a simple **while** statement which sums the elements of variable `xs`, storing the result in variable `r`. A loop invariant is given which establishes that variable `i` is non-negative.

**Notes.** When multiple **where** clauses are given, these are combined using a conjunction to form the loop invariant. The combined invariant must hold on entry to the loop and after each iteration. Thus, when the condition evaluates to `false`, the loop invariant is guaranteed to hold. However, the loop invariant need not hold when the loop is exited using a **break** (§5.3.1) statement.

# Chapter 6

## Expressions

The majority of work performed by a Whiley program is through the execution of *expressions*. Every expression produces a *value* and may have additional side effects.

### 6.1 Evaluation Order

The operands for operators in Whiley are evaluated in a specific left-to-right *evaluation order*. This always respects parentheses and operator precedence. Furthermore, aside from the short-circuiting operators (§6.10.2), operands are always fully evaluated before any part of the operation is performed.

#### 6.1.1 Operator Precedence

To determine the evaluation order for mixed-operator expressions without explicit parenthesis, a fixed *operator precedence* is used. This is first determined by *operator class*:

1. **Unary Expressions.** This operator class represents operators which take exactly one operand. This class takes highest precedence, and includes operators such as arithmetic negation (§6.4.1) and logical not (§6.10.1).
2. **Binary (Infix) Expressions.** This operator class represents operators which accept two operands with an infix syntax. This class includes the usual range of common binary operators, such as arithmetic operators (§6.4.3, §6.4.4), logical connectives (§6.10.2), etc.
3. **Binary (Mixfix) Expressions.** This operator class represents operators which accept two operands but which are non-infix operators and, hence, precedence is not ambiguous. This class includes the array access (§6.11.2) and range operators (§??).

4. **N-Ary Expressions.** This operator class represents operators which accept an arbitrary number of operands. This class includes array constructors (§??), record constructors (§6.12.2), etc.

Within the class of binary infix expressions, an explicit precedence rank is given for each operator:

1	<div>*</div> <div>/</div>
2	<div>+</div> <div>-</div>
3	<div>==</div> <div>!=</div> <div>&lt;</div> <div>&lt;=</div> <div>&gt;=</div> <div>&gt;</div>
4	<div>&amp;</div>
5	<div> </div>
6	<div>^</div>
7	<div>&amp;&amp;</div>
8	<div>  </div>
9	<div>==&gt;</div>
10	<div>&lt;==&gt;</div>

Lower ranked operators bind more tightly (i.e. take higher precedence) than higher ranked operators.

## 6.2 Expressions

A multi-expression is an expression composed of two or more unit expressions and which returns a tuple value (§4.5). The operands of a multi-expression are evaluated in a strict left-to-right order.

```
Expr ::= UnitExpr (   UnitExpr )*
```

**Example.** The following example illustrates the use of a multi-expression:

```
1 function scale(real x, real y, real p) -> (real,real):  
2   return (x*p), (y*p)
```

This function accepts three **real** values and returns two. In the body, the **return** statement contains a multi-expression which produces a tuple composed of two **real** values.

## 6.3 Unit Expressions

A unit expression is an expression which returns exactly one value. There is a large range of possible unit expressions, including comparators, arithmetic operators, logical operators, etc.

```
UnitExpr ::= ArithmeticExpr  
          | BitwiseExpr  
          | CastExpr  
          | EqualityExpr  
          | InvokeExpr  
          | LambdaExpr  
          | LogicalExpr  
          | ArrayExpr  
          | RecordExpr  
          | ReferenceExpr  
          | TermExpr
```

## 6.4 Arithmetic Expressions

Arithmetic expressions operate on values of numeric type (either **int** or **real**).

```
ArithmeticExpr ::= ArithmeticNegationExpr  
                | ArithmeticRelationalExpr  
                | ArithmeticAdditiveExpr  
                | ArithmeticMultiplicativeExpr
```

## 6.4.1 Negation Expressions

A negation expression accepts one argument of numeric type and produces a result of matching type. Specifically, the *negation operator* mathematically negates the given value, which is always equivalent to subtracting the operand from zero.

```
ArithmeticNegationExpr ::= - UnitExpr
```

**Example.** The following illustrates the negation operator:

```
1 function negAccess(int i, [int] items) -> int
2 requires -|items| <= i && i < |items|:
3 //
4 if i < 0:
5     return -items[-(i+1)]
6 else:
7     return items[i]
```

## 6.4.2 Relational Expressions

Relational expressions are either *strict* (where only inequality is tested) or *non-strict* (where both equality and inequality are tested). The *less-than comparator*,  $<$ , and *greater-than comparator*,  $>$ , are strict. Conversely, the *less-than-or-equal comparator*,  $<=$ , and *greater-than-or-equal comparator*,  $>=$ , are non-strict.

```
ArithmeticRelationalExpr ::=
    | UnitExpr < UnitExpr
    | UnitExpr <= UnitExpr
    | UnitExpr => UnitExpr
    | UnitExpr > UnitExpr
```

**Example.** The following example illustrates the strict inequality comparators:

```
1 function compare(int x, int y) -> int:
2     if x < y:
3         return -1
4     else if x > y:
5         return 1
6     else:
```

```
7 return 0
```

This function compares two integer arguments and returns the “sign” of their comparison. The strict inequality comparators are used so the case where  $x == y$  can be distinguished.

### 6.4.3 Additive Expressions

An additive expression accepts two arguments of identical type (either `int` or `real`) and produces a result of matching type. The *addition operator*, `+`, adds both arguments together whilst the *subtraction operator*, `-`, subtracts its right argument from its left argument.

```
ArithmeticAdditiveExpr ::= UnitExpr ( + | - ) UnitExpr
```

**Example.** The following illustrates the additive operators:

```
1 function diff(int a, int b) -> int:  
2   return a - b
```

This function simply computes the difference between its two arguments using the subtraction operator.

### 6.4.4 Multiplicative Expressions

A multiplicative expression accepts two arguments of identical type (either `int` or `real`) and produces a result of matching type. The *multiplication operator*, `*`, multiplies both arguments together whilst the *division operator*, `/`, divides its left argument by its right argument. Finally, the *remainder operator* returns the remainder of its operands from an implied division.

```
ArithmeticMultiplicativeExpr ::= UnitExpr ( * | / | % ) UnitExpr
```

**Example.** The following illustrates the remainder operator:

```
1 function indexOf([int] xs, int i) -> int  
2 requires i >= 0 && |xs| > 0:  
3   //  
4   return xs[i % |xs|]
```

This function accepts a non-negative integer and uses this to index into an array. To ensure the array access is within bounds, the remainder operator is used. Furthermore, the function requires the array is non-empty to prevent a fault with the remainder operator.

**Notes.** For division, the right operator must be non-zero otherwise a fault is raised, and likewise for remainder. For integer division, the result is rounded towards zero. For a remainder operation, the result may be negative (e.g. `-4 % 3 == -1`).

## 6.5 Bitwise Expressions

Bitwise expressions operate on values of **byte** type.

```
BitwiseExpr ::= BitwiseComplementExpr
              | BitwiseBinaryExpr
              | BitwiseShiftExpr
```

### 6.5.1 Complement Expressions

The *bitwise complement operator* accepts an argument of **byte** type (§4.4.3) and produces a result of matching type. The operator returns bitwise complement of the argument; that is, where the sign of each bit is reversed.

```
BitwiseComplementExpr ::=  UnitExpr
```

**Example.** The following example illustrates the bitwise complement operator:

```
1 // Check whether a given bit is zero
2 function isZero(byte b, int bit):
3     byte mask = 1b << bit
4     return (b & ~mask) == b
```

### 6.5.2 Binary Expressions

A bitwise binary expression operates on values of **byte** type (§4.4.3). The *bitwise AND* operator, `&`, performs a logical AND between the respective bits of each operand, and produces a **byte**. The *bitwise OR* operator, `|`, performs a logical OR between the respective bits of each operand, and produces a **byte**. The *bitwise exclusive-OR* operator,

$\wedge$ , performs a logical exclusive-OR between the respective bits of each operand, and produces a **byte**.

```
BitwiseBinaryExpr ::= UnitExpr (  |  |  ) UnitExpr
```

**Example.** The following example illustrates the bitwise OR operator:

```
1 constant AF is 4
2 constant ZF is 6
3
4 function setFlag(byte flags, int flag) -> byte:
5     byte mask = 1b << flag
6     return flags | mask
7
8 function getFlag(byte flags, int flag) -> bool:
9     byte mask = 1b << flag
10    return (flags & mask) != 0
```

These functions provide mechanisms for manipulating a byte of “flags”, as determined by the constant identifiers. The bitwise OR operator is used to ensure a given bit is set, whilst the bitwise AND operator is used to check whether one is set or not. This example also illustrates the left-shift operator (§6.5.3).

### 6.5.3 Shift Expressions

A bitwise shift expression accepts an argument of **byte** type (left) and one of **int** type (right) and produces a value of **byte** type. The *left shift operator*,  $\ll$ , shifts the bits of a **byte** in an upwards direction, such that the most significant bit is discarded and the least significant bit assigned 0. The *right shift operator*,  $\gg$ , shifts bits in a downwards direction, such that the least significant bit is discarded and the most significant bit assigned 0.

```
BitwiseShiftExpr ::= UnitExpr [ (  |  ) UnitExpr ]
```

**Examples.** The following illustrates the left shift operator:

```
1 public function toUnsignedByte(u8 v) -> byte:
2     //
3     byte mask = 00000001b
4     byte r = 0b
```

```

5  int i = 0
6  while i < 8:
7      if (v % 2) == 1:
8          r = r | mask
9          v = v / 2
10         mask = mask << 1
11         i = i + 1
12 return r

```

This function accepts an integer between 0 and 255 and converts this into an appropriate bit representation. The left shift operator is used to maintain an internal mask for the bit currently being initialised.

## 6.6 Cast Expressions

A *cast operator* accepts a value of one type and returns a value of a different, but equivalent, type and this may result in a change of the underlying representation.

```

CastExpr ::= ( DefiniteType ) Expr

```

**Example.** The following illustrates a cast operator being used:

```

1  function f(IntPoint p) -> RealPoint:
2      return (RealPoint) p
3

```

This function converts a record containing two *int* fields into one containing two *real* fields using a cast.

## 6.7 Equality Expressions

The *equality comparator*, `==`, tests whether two values are equal. Likewise, the *inequality comparator*, `!=`, tests whether two values are *not* equal.

```

EqualityExpr ::=
    | Expr == Expr
    | Expr != Expr

```

**Example.** The following example illustrates an equality expression:

```
1  function contains([int] items, int item) -> bool:
2      //
3      int i = 0
4      while i < |items|:
5          if i == item:
6              return true
7          i = i + 1
8      return false
```

This function checks whether a given integer is contained in an array of integers. This is done by iterating each element of the array and comparing it against the given item.

## 6.8 Invoke Expressions

A *function or method invocation* executes a named function or method declared in a given source file. An *indirect function or method invocation* executes a function determined by a given expression. An invocation passes arguments of appropriate number and type to the executed function or method. An invocation may also return one or more values which can be subsequently used.

```
InvokeExpr ::= Name ( ArgsList )
IndirectInvokeExpr ::= UnitExpr ( ArgsList )

ArgsList ::= [ UnitExpr ( , UnitExpr )* ]
```

**Example.** The following example illustrates a function invocation:

```
1  // Determine the max of two values
2  function max(int x, int y) -> int:
3      if x >= y:
4          return x
5      else:
6          return y
7
8  // Determine the max of 1 or more values
9  function max([int] items) -> int
10 requires |items| > 0:
11     //
```

```

12  int r = 0
13  nat i = 0
14  while i < |items|:
15      r = max(r, items[i])
16      i = i + 1
17  //
18  return r

```

This example illustrates one function being called from another. Both functions have the same name and are said to *overload* one another. Function resolution identifies the appropriate function based on the number and type of arguments supplied.

## 6.9 Lambda Expressions

A *lambda expression* creates an anonymous function or method which can accept zero or more arguments and whose return type is inferred from the body of the lambda.

$$\text{LambdaExpr} ::= \& \big( (\text{Type Ident})^* \rightarrow \text{Expr} \big)$$

**Example.** The following example illustrates a lambda expression:

```

1  // Type of function which accepts and returns an int
2  type fun_t is function(int) -> int
3
4  // Apply a function to every element of a list
5  function map(fun_t fn, [int] xs) -> [int]:
6      int i = 0
7      while i < |xs|:
8          xs[i] = fn(xs[i])
9          i = i + 1
10     return xs
11
12  // Add y to every element of items
13  function addAll([int] items, int y) -> [int]:
14      fun_t fn = &( int x -> x + y )
15      return map(fn, items)

```

This function illustrates the classical *map* function which applies a function to all elements of a collection. In this case, a lambda is used to create a function which adds a constant value to its argument. This lambda is used to implement `addAll()` in terms of `map()`.

## 6.10 Logical Expressions

Logical expressions operate on values of `bool` type.

```
LogicalExpr ::=
    | LogicalNotExpr
    | LogicalBinaryExpr
    | LogicalQuantExpr
```

### 6.10.1 Not Expressions

The *logical not* operator accepts an argument of `bool` type and produces a value of `bool`. The value returned is the logical opposite of the argument.

```
LogicalNotExpr ::= ! UnitExpr
```

**Example.** The following example illustrates the logical not operator:

```
1 function max(int a, int b):
2     if !(a < b):
3         return a
4     else:
5         return b
```

This function computes the maximum of two `int` values. The expression `!(a < b)` is equivalent to `a >= b` and is used purely to illustrate the logical not operator.

### 6.10.2 Connective Expressions

A logical connective operates on values of `bool` type (§4.4.2) to produce another `bool` value. The *if-and-only-if (iff)* operator, `<==>`, returns `true` if either both operands are `true` or both are `false`. The *implication* operator, `==>`, returns `true` if either the left operand is `false`, or both operands are `true`. The *logical OR* operator returns `true` if either operand is `true`, whilst the *logical AND* operator returns `true` if both operands are `true`.

```
LogicalBinaryExpr ::= UnitExpr ( <==> | ==> | && | || ) UnitExpr
```

**Example.** The following examples illustrate some of the logical operators:

```

1  function implies(bool x, bool y) -> bool:
2      return !x || y
3
4  function iff(bool x, bool y) -> bool:
5      return implies(x,y) && implies(y,x)

```

The function `implies()` implements the well-known equivalence between implication and logical OR. The function `iff()` implements the well-known equivalence between implication and `iff`.

### 6.10.3 Quantifier Expressions

A quantifier operates over an array of values and produces a value of `bool` type. The *universal quantifier*, `all`, returns `true` if the given expression evaluates to `true` for every element in the array, and `false` otherwise. The *existential quantifier*, `exists`, returns `false` if the given expression evaluates to `false` for every element in the array, and `true` otherwise. The *inverted universal quantifier*, `no`, returns `true` if the given expression evaluates to `false` for every element in the array, and `false` otherwise

**Examples.** The following examples illustrate the universal quantifier:

```

1  // A type representing lists of natural numbers
2  type natlist is ([int] xs) where
3      all { i in 0 .. |xs| | xs[i] >= 0 }

```

Here, the type `natlist` represents those integer arrays for which every element is a natural number (i.e. greater-or-equal to zero).

### 6.11 Array Expressions

Array expressions operate on values of array type (e.g. `int []`, `(bool|real) []`, etc).

```
ArrayExpr ::=
    | ArrayLengthExpr
    | ArrayAccessExpr
    | ArrayGeneratorExpr
    | ArrayInitialiserExpr
```

### 6.11.1 Length Expressions

The *lengthof operator* accepts a value of array type, and produces a value of **int** type which equals the number of elements in the array.

```
ArrayLengthExpr ::= [ Expr ]
```

**Example.** The following examples illustrate the lengthof operator:

```
1 // Return first item in list over a given item
2 function firstOver([int] items, int item) -> int|null:
3     int i = 0
4     while i < |items|:
5         if items[i] > item:
6             return item
7         i = i + 1
8     // no match
9     return null
```

The above function iterates through all elements in an array looking for the first which is above a given item. The length operator is used to ensure this iteration remains within bounds.

### 6.11.2 Access Expressions

An array access expression accepts a array argument with one operand and produces a value of the array element type. The *index-of operator* returns the element at the given operand position in the array.

```
ArrayAccessExpr ::= UnitExpr [ Expr ]
```

**Examples.** The following example illustrates the array access operator:

```
1 // Recursively compute the sum of a list
2 function sum([int] items) -> int:
3     if |items| == 0:
4         return 0
5     else:
6         return items[0] + sum(items[1..|items|])
```

**Broken?** The above function computes the sum of an array by recursively breaking it down in successively smaller arrays. The access operator is used to get the first item in the array at each stage.

### 6.11.3 Generator Expressions

An *array generator* accepts two arguments and produces a value of array type. The second argument must be of `int` type and the array produced contains exactly this many occurrences of the first argument.

```
ArrayGeneratorExpr ::= [ UnitExpr ; UnitExpr ]
```

**Examples.** The following example illustrates an array generator:

```
1 function cons(int head, [int] tail) -> [int]:
2     [int] r = [head; |tail| + 1]
3     int i = 0
4     //
5     while i < |tail|:
6         r[i+1] = tail[i]
7         i = i + 1
8     //
9     return r
```

This function constructs a array by prepending a given element onto the front of a given array. The array generator is used to construct the initial array of values whose size is one larger than the given array.

### 6.11.4 Array Initialiser

An *array initialiser* accepts zero or more operands and produces a value of array type. Array initialisers are used to construct arrays from their constituent elements.

```
ArrayInitialiserExpr ::= [ ArgsList ]
```

**Example.** The following example illustrates an array initialiser:

```
1  constant digits is ['0','1','2','3','4','5','6','7','8','9']
2
3  // Convert an integer value into a string
4  function toString(int item) -> [int]:
5      [int] r = []
6      //
7      while item != 0:
8          int v = item / 10
9          int w = item % 10
10         r = [digits[w]] ++ r
11         item = v
12     //
13     return r
```

The above function converts an integer value into its string representation. An array initialiser is used to map integer values to their corresponding digits. An empty array initialiser is also used to initialise the string.

## 6.12 Record Expressions

Record expressions operate on values of record type (e.g. {**int** x, **int** y}, etc).

### 6.12.1 Access Expressions

The field access operator accepts a value of record type and returns the value held in a given field.

```
FieldAccessExpr ::= UnitExpr . Ident
```

**Examples.** The following example illustrates a field access expression constructor:

```
1  type Vec is {int x, int y, int z}
2
3  function dotProduct(Vec v1, Vec v2) -> Vec:
4      return (v1.x * v2.x) + (v1.y * v2.y) + (v1.z * v2.z)
```

The above function computes the so-called *dot product* of two vectors. The field access operator is used to access the three fields of each vector.

### 6.12.2 Record Initialisers

A *record initialiser* accepts one or more operands and produces a value of record type. Record constructors are used to construct records from their constituent elements.

```
RecordInitialiserExpr ::= { FieldArgsList }  
  
FieldArgsList ::= Ident : UnitExpr ( , Ident : UnitExpr )*
```

**Example.** The following example illustrates a record initialiser:

```
1 type Point is {int x, int y}  
2  
3 // Translate a given point based on a delta in x and y  
4 function move(Point p, int dx, int dy) -> Point:  
5     return { x: p.x+dx, y: p.y+dy }
```

The above function simply translates a `Point` from one position to another based on a shift in `x` and in `y`. The record initialiser is used to construct the new `Point`.

## 6.13 Reference Expressions

Reference expressions operate on values of reference type (e.g. `&int`).

### 6.13.1 New Expressions

A new expression accepts an argument of any type and produces a reference to that type. The *new operator* allocates sufficient space on the heap and initialises it with the given value. It then returns a reference to this heap object.

```
NewExpr ::= new UnitExpr
```

**Example.** The following example illustrates the new operator:

```
1 type LinkedList is null | &{LinkedList next, int data}  
2
```

```

3 // Add a new item onto the head of the list
4 method add(LinkedList list, int item) -> LinkedList:
5 //
6     return new {next: list, data: item}

```

This example illustrates an operation for adding an item onto the front of a classical linked list. Here, a `LinkedList` is either `null` or a reference to a node containing a `next` reference and `data` item. The `add` operation simply allocates a new node and places it on the front of the list.

### 6.13.2 Dereference Expressions

A dereference expression accepts an argument of reference type and returns a value (or element) of the reference's target type. The *dereference operator* returns the value referenced by the argument. The *arrow operator* returns a field of the value referenced by the argument.

```

DereferenceExpr ::= * TermExpr
                  | UnitExpr -> Ident

```

**Example.** The following illustrates the dereference operator:

```

1 type LinkedList is null | &{LinkedList next, int data}
2
3 method length(LinkedList l) -> int:
4 //
5     if l is null:
6         return 0
7     else:
8         return 1 + length(l->next)

```

This method traverses a linked list counting the number of links it contains. The arrow operator is used to access the next link in the chain.

**Notes.** The arrow operation “`e->f`” is a short-hand notation for “`(*e).f`” and can be used when `*e` has effective record type (§4.15.2).

## 6.14 Terminal Expressions

A *terminal expression* is one which can terminate an expression tree (though does not necessarily do so). For example, a numeric literal represents a terminal node in an expression tree.

```
TermExpr ::= Ident  
          | Literal  
          | ( Expr )
```

## Chapter 7

# Flow Typing

The Whiley programming language is *statically typed*, meaning that every expression has a type determined at compile time. Furthermore, evaluating an expression is guaranteed to yield a value of its type. Whiley's *type system* governs how the type of any variable or expression is determined. Whiley's type system is unusual in that it operates in a *flow-sensitive* manner allowing variables to have different types at different program points.

## Chapter 8

# Definite Assignment

See error reported for this check §10.3.4.

```
1  function f(int x) => int:
2      int y
3      if x < 0:
4          y = 1
5      return x + y
```

```
1  function f(int x) => int:
2      int y
3      while x < 0:
4          y = 1
5          x = x + 1
6      return x + y
```

## Chapter 9

# Verification

The Whiley programming language supports *specifications* on functions, methods and data types which can be *statically verified* at compile time. Verification operates in an intra-procedural fashion based on a modified and extended version of Hoare logic<sup>[19]</sup>. To benefit from verification, programmers must provide specifications for their functions, methods and data types; additionally, they must provide loop invariants and other *assertions* to guide the verifier.

# Chapter 10

## Error Messages

### 10.1 Parse Errors

### 10.2 Declarations

#### 10.2.1 “Cyclic Constant Declaration” (301)

A *cyclic constant declaration* occurs when a constant declaration refers to itself, either *directly* or *indirectly*. This is an error because constants must be evaluated at *compile time*.

**Example.** The following illustrates several cyclic constant declarations:

```
1 constant const1 is 1 + const1
2
3 constant const2 is 1 + const3
4 constant const3 is 1 + const2
```

Here, all three constant declarations are cyclic. The declaration for `const1` has a *direct* cycle, because its definition refers to itself. The declaration for `const2` has an *indirect* cycle, because its definition refers to `const3` which, in turn, refers back to `const2`.

## 10.3 Expressions

### 10.3.1 “Invalid File Access” (000)

### 10.3.2 “Invalid Package Access” (000)

### 10.3.3 “Resolution Error” (000)

### 10.3.4 “Variable Possibly Uninitialised” (000)

A *variable possibly uninitialised* occurs when a variable may be used without being defined. That is, when a simple path exists through the control-flow graph of a function or method from that variable’s declaration to a use which contains no definition for that variable. This error is reported as part of the *definite assignment* checking performed during compilation (see §8).

**Example.** The following illustrates a variable which is possibly uninitialised:

```
1 function f(int x) => int:  
2   int y  
3   return x + y
```

Here, variable `y` is definitely uninitialised in the expression “`x + y`”. For more examples of variables which are possibly uninitialised, see §8.

### 10.3.5 “Ambiguous Coercion” (000)

## 10.4 Control Flow (000)

### 10.4.1 “Invalid LVal” (000)

### 10.4.2 “Invalid Tuple LVal” (000)

### 10.4.3 “Break Outside of Loop” (000)

### 10.4.4 “Unknown Variable” (000)

### 10.4.5 “Unknown Function or Method” (000)

### 10.4.6 “Variable Already Defined” (000)

A *variable redefinition* occurs when a variable is declared with a name matching another variable already in scope. This is an error because it is not permitted for one variable to shadow another.

**Example.** The following illustrates an example of a variable redefinition:

```
1  function add([int] xs, int v) => [int]:  
2      for k,v in xs:  
3          xs[k] = xs[k] + v  
4      return xs
```

Here, the **for** loop attempts to declare a variable *v*, but another variable *v* was already declared as a parameter.

### 10.4.7 “Duplicate Default Label” (000)

A *duplicate default label* occurs when a **switch** statement includes more than one **default** label. This is an error because at most one **default** is permitted.

**Example.** The following illustrates an example of a duplicate **default** label:

```
1  function f(int x):  
2      switch x:  
3          case 0:  
4              return 0  
5          default:  
6              return 1  
7          default:  
8              return 2
```

Here, the **switch** statement has two **default** labels. This must be an error as, otherwise, it would be ambiguous as to which executed.

### 10.4.8 “Duplicate Case Label” (000)

A *duplicate case label* occurs when a **switch** statement includes more than one **case** label matching the same value. This is an error because at most one **case** matching a given value is permitted.

**Example.** The following illustrates an example of a duplicate **case** label:

```
1  function f(int x):  
2      switch x:  
3          case 0:  
4              return 0  
5          case 0,1:  
6              return 1  
7          default:  
8              return 2
```

Here, the **switch** statement has two **case** labels, both of which match the value 0. This must be an error as, otherwise, it would be ambiguous as to which executed.

## 10.4.9 “Unreachable Code” (000)

In a function or method, *unreachable code* arises when no possible execution path could reach them.

**Example.** The following illustrates some unreachable code:

```
1  function abs(int x):  
2      //  
3      if x < 0:  
4          return -x  
5      else:  
6          return x  
7      //  
8      return 0 //unreachable
```

Here, the final **return** statement can never be reached by any execution path through the `abs()` function. This is considered an error because it indicates something undesirable which may not have been intended.

**10.4.10 "Missing Return Value" (000)**

**10.4.11 "Branch Always Taken" (000)**

## **10.5 Functions (000)**

**10.5.1 "Reference Not Permitted in Function" (000)**

**10.5.2 "Method Invocation Not Permitted In Function" (000)**

**10.5.3 "Reference Access Not Permitted in Function" (000)**

**10.5.4 "Return from Void" (000)**

## **10.6 Types (000)**

**10.6.1 "Subtype Error" (000)**

**10.6.2 "Incomparable Operands" (000)**

**10.6.3 "Record Type Required" (000)**

**10.6.4 "Record Missing Field" (000)**

# Glossary

- access control** Mechanisms for restricting the visibility of named declarations. 17
- assertion** An assertion statement is specified with the **assert** keyword and identifies a condition which must hold at that point for all possible executions. 73
- block comment** A block comment begins with “/\*” and continues until the end-of-comment marker “\*/”. 10
- boolean expression** An expression which evaluates to a value of type **bool**. 18, 40, 41, 46, 82
- compilation group** A group of one or more source files being compiled together. 15, 81
- compilation unit** A single unit of compilation. In Whiley, this includes source files and also binary WyIL files. 15–17
- compile time** The point in time at which a given compilation group is compiled into binary form.. 75
- compound statement** A statement (e.g. **if**, **while**, etc) which may contain blocks of other statements. 39
- constant declaration** A source-level declaration which associates a name with a constant expression. The full name of the declared entity is determined from the package and name of the enclosing source file.. 16, 75
- contractive** A type is contractive if it does not describe an infinite series of self applications.. 18
- declaration** A declaration defines a new named entity within its enclosing source file.. 17, 18, 81
- declaration modifier** A declaration modifier provides additional meaning to a declaration.. 17

- default package** The top-level package which has no name, and is considered to be a “global” package.. 16
- expression** A combination of constants, variables and operators that, when evaluated, produce a single value. Expressions in certain circumstances may have side effects. 51, 81, 83, 84
- fault** A fault is raised when an unrecoverable error in the program occurs. For a verified program, no faults are possible except to indicate an out-of-memory failure.. 40, 41, 56
- foreign function interface** A mechanism provided to enable inter-operation between Whyley source files and source files written in other languages.. 18
- function declaration** A source-level declaration which defines a named function. The full name of the declared entity is determined from the package and name of the enclosing source file.. 16
- indentation syntax** A lexical organisation of source files where indentation is significant and is used to group statements and blocks. 9
- intersection type** A type formed by combining two or more types together (e.g. `[int] & [any]` such that it includes any value contained in both. 23
- line comment** A line comment begins with “//” and continues until the end of line. 10
- literal** A source-level entity which describes a value of primitive type. 11
- loop invariant** A boolean expression which must hold on every iteration of a loop. 19, 20, 45, 48, 73
- method declaration** A source-level declaration which defines a named method. The full name of the declared entity is determined from the package and name of the enclosing source file.. 16
- name mangling** The process of encoding information (e.g. about type parameters) within the exported name of a declaration.. 18
- name resolution** The process of determining the fully qualified name of an identifier within a source file. Names are first resolved within the same source file, and then by searching the list of imported entities in reverse order. 17
- negation type** A type formed from another (e.g. `!int`), such that it includes any value not contained in the other. 23

- overloading** Overloading occurs when two entities in the same category exist with the same name, and is permitted only when their type allows for disambiguation.. 16
- package** A unit of hierarchical organisation within the Whiley namespace.. 15
- postcondition** A logical condition over the parameters and returns of a function or method which must be true immediately after execution of that function or method.. 19, 20, 33, 47
- precondition** A logical condition over the parameters of a function or method which must be true immediately prior to execution of that function or method.. 19, 20, 32
- safety critical system** A system which operates in a high-risk setting where failure can lead to loss of life, injury, significant damage or environmental harm. 7
- source file** A file in which source code is located. Source files for the Whiley programming language have the extension `.whiley`. In Whiley, source files must be compiled into a binary form before they can be executed.. 9, 15, 18–20, 32, 81–84
- statement** An program instruction which has an effect on the environment when executed, but does not produce a value. 39, 83
- statement block** A sequence of zero or more consecutive statements with the same indentation. 10, 39, 46
- type** An abstract entity which represents the set of values a given variable may hold, or a given expression may evaluate to.. 23, 82–84
- type declaration** A source-level declaration which associates a name with a type descriptor. The full name of the declared entity is determined from the package and name of the enclosing source file.. 16
- type descriptor** A source-level description of an underlying type. Unlike many languages, type descriptors and types are quite distinct in Whiley as, for example, two distinct descriptors may describe the same underlying type. 23, 83
- type pattern** A source-level description of an underlying type (similar to a type descriptor) where one or more variables are associated with its subcomponent(s).. 24
- union type** A type formed by combining two or more types together (e.g. `int | null`), such that it includes any value contained in either. 23

**value** A value is an instance of a given type and permits a specific set of operations. Examples include: the integer value 1; the list value [1, 2]; and the **null** value.. 51

**variable declaration** A statement which declares one or more variable(s) for use in a given scope. Each variable is given a type which limits the possible values it may hold, and may not already be declared in an enclosing scope. 43, 84

**variable initialiser** An optional expression used to initialise variable(s) declared as part of a variable declaration. 43

**verifying compiler** A compilers which employs automated mathematical and logical reasoning to check the correctness of the programs that it compiles. 7

**WyIL file** A compiled (i.e. binary) form of a Whyley source file. 15, 81
